Abstract

Eight new species of fungi (Acanthobasidium norvegicum, Amylocorticium laceratum, Hyphodermula transiens, Odonticium septocystidiatum, Phlebia cretacea, Ph. subulata, Stecherinum albidum, and Tubulicrinis calothrix) were identified for Poland after a study of collections from large forests situated in the northeast part of the country. Leptosporomyces fuscostratus was confirmed for Polish mycobiota. Main diagnostic features, natural range, substratum preferences, and taxonomic position of these species are discussed. Color images of basidiomata for 9 species, line drawings of microscopic structures for 6 species, and scanning electron microscopy images of important microstructures for 4 species are provided.

Key words: Aphyllophorales; geography; micromorphology; Polyporales; wood decay basidiomycetes

Running head: Corticioid fungi from Białowieża forest

Introduction

Corticioid fungi is an artificial assemblage of the species from the phylum Basidiomycota and class Agaricomycetes, characterized by effused or effused-reflexed basidiomata, one-celled basidia, and hymenophore of various configurations, from smooth to raduloid and reticulately folded, but excluding poroid and lamellate types. Many of these fungi have flat, thin fruitbodies, that develop on dead wood in all seasons, excluding frost periods. They are considered by mycologists as a separate group, accepted historically on the basis of similar macromorphology of basidiomata, ecology, and methodical approaches for study of species. We accept a brief definition of corticioid fungi (Yurchenko, 2020) as non-poroid resupinate Aphyllophorales, following Jülich and Stalpers (1980), and including one genus of Tremellomycetes, Syzygospora. The latter has a peculiar morphology of basidia, resembling true homobasidia, and the ability of some species to develop very small film-like basidiomata. We also belong Dentipratulum, a genus with hydnoid hymenophore, to corticioid fungi, because its fructifications have scarce subiculum (see Holec & Zehnálek, 2021).

Species diversity of corticioid fungi in Poland is relatively well studied. The monograph by Wojewoda (2003) is the most recent catalogue of the all the larger basidiomycetes, found in Poland. It includes 293 species of corticioid fungi as defined above. However, new species are recorded almost every year for the country.

Białowieża Primeval Forest is one of the largest and best-preserved non-montane deciduous forest massif in Europe (Bobiec, 2002). It is an area of particular interest for
mycologists (Ruszkiewicz-Michalska et al., 2021) due to its old-aged ecosystems, scarcely modified by human activity, that include both nemoral (associated with e.g. *Quercus robur*) and boreal (associated with *Picea abies* and *Pinus sylvestris*) elements of biota. Larger basidiomycetes have been studied here since 1826, but a monographic treatment of corticioid fungi has not been realized yet (see Kujawa et al., 2018).

In the present paper we give the characteristics of some new species thereby adding to the list of Polish fungi.

**Material and Methods**

The new species for Polish mycobiota were identified after microscopic examination of 540 specimens of corticioid fungi, stored in the herbarium of Institute of Forest Sciences, Białystok University of Technology (BLS, Hajnówka). These specimens were collected by Marek Wołkowycki from the northeast part of Poland, in the period 1993–2022; most collections belong to the years 2018–2020. About 95% of the specimens examined were collected in Białowieża Primeval Forest (southeast part of Podlaskie voivodeship), 1% in Knyszyn Primeval Forest (central-east part of Podlaskie voivodeship), and 4% in Piska Primeval Forest (southeast part of Warmińsko-Mazurskie voivodeship).

Macro- and micromorphology was studied on dry basidiomata. The pictures of fresh basidiomata of some species taken soon after their collection were also used to document macromorphology. For microscopic slides, vertical hand sections of the basidiomata were rehydrated in 3% aqueous potassium hydroxide (abbreviated as KOH in the text). Incrustations on hyphae and hynenial elements and amyloid reaction of basidiospores were studied in Melzer’s reagent, wherever necessary. Microscopic measurements were done on Nikon Eclipse Ni-U light microscope (Nikon Corp., Japan), mostly under ×1000 magnification, by NIS-Elements Br imaging software (Nikon Corp.). Spore quotient (Q) was determined as length/width ratio for individual spores.

Scanning electron images of selected microstructures of the fungi were obtained on Phenom G2 pro desktop microscope (Labmate, UK). For these images, pieces of fruitbodies were taken from the herbarium, glued to metallic stands using double-sided adhesive film, and coated with 3.1‒3.2 nm layer of gold in a Leica EN ACE200 vacuum coater (Leica Microsystems, Germany).

To confirm that a species was not published for the country before, we used the checklist of Wojewoda (2003), and a checklist in the resource grzyby.pl (Snowarski, 2022). Some additional data on species distribution were taken from the Global Biodiversity Information Facility (https://www.gbif.org).

**Results**

The study revealed that eight species of fungi identified by us had not been published in articles or monographs for Poland earlier. Besides, we found that one species, *Leptosporomyces fuscostratus*, required clarification of its status in Polish biota. The data about these species are given below.
**Acanthobasidium norvegicum** (J. Erikss. & Ryvarden) Boidin, Lanq., Cand., Gilles & Hugueney (Stereaceae, Russulales)

Syn. *Aleurodiscus norvegicus* J. Erikss. & Ryvarden

Figures 1A, 3A; 4

The species is distinguished by the following main features: poorly developed subiculum (10–25 μm thick); numerous subcylindrical or fusoid cystidia, having pale brownish-yellow granular or resinous contents in water and KOH; presence of acanthophyses; (1)2-sterigmate basidia; large (9–12 μm long) amyloid basidiospores, covered by warts, easily observable in Melzer’s reagent. Some basidia have scarce, short lateral protuberances in their lower half. Occasional basidia have a transverse secondary septum. The acanthophyses of this fungus resemble basidia in shape. Our specimen exhibited mostly 2 apical protuberances on acanthophyses, whereas in pictures published by other authors (Larsson & Ryvarden, 2021; Martini, 2016) the number of protuberances reached 4–7. Spores of this fungus look almost smooth in KOH.

This species is distributed in Western Europe, from Norway and Sweden to Portugal (Bernicchia & Gorjón, 2010; Eriksson & Ryvarden, 1973). Our locality is the easternmost known for the species.

The usual substrata for this species are dead *Calluna* stems and twigs (Eriksson & Ryvarden, 1973). The fungus was reported on *Rubus* in France (Wu et al., 2001).

In molecular phylogeny studies (Tian et al., 2018; Wu et al., 2001), it was proposed to belong *Aleurodiscus norvegicus* to the derivative genus *Acanthobasidium* together with *A. phragmitis* Boidin, Lanq., Cand., Gilles & Hugueney and *A. weirii* (Burt) L.D. Dai & S.H. He. The generic name indicates that some basidia in *A. norvegicus* have lateral protuberances, and supposedly acanthophyses are immature basidia (Eriksson & Ryvarden, 1973; Martini, 2016).

**Specimen examined**: Białowieża Primeval Forest, near Topiło village, compart. No. 574Ch, Vaccinio uliginosi-Pinetum, on dead corticated twigs of *Vaccinium uliginosum*, 1–5 mm diam., coll. M. Wołkowycki, 2 XI 2019 (BLS M-3535).

**Amylocorticium laceratum** (Litsch.) Hjortstam & Ryvarden (Amylocorticiaceae, Amylocorticiales)

Figures 1B, 5

Syn. *Athelopsis lacerata* (Litsch.) J. Erikss. & Ryvarden

The species is distinguished by white, pellicular basidiomata, comparatively narrow hyphae [1.3–2.5(–3.5) μm], substipitate-clavate basidia, and allantoid, but relatively broad spores (Q=2.7–3.3) with well pronounced apiculus and amyloid reaction. Basidia usually have maximal width near their middle part; sterigmata of basidia are short and wide throughout most of their development period. Spores in our specimen turn bluish with pale yellow hue in Melzer’s reagent. Additional notable feature is the minutely guttulate contents of hyphae in KOH. Our specimen showed encrusted subhymenium, while this feature was not noted for the species earlier (Eriksson & Ryvarden, 1973; Zmitrovich, 2008). Eriksson and Ryvarden (1973) indicated non-granular protoplasm in the basidioles to be a diagnostic character, but in our specimen hymenial elements are minutely guttulate or granular in water and KOH. Spores in our specimen (6–8 × 2.7–3.3 μm) are somewhat larger, than in descriptions of *A. laceratum* (6–7 × 2.5 μm; Bernicchia & Gorjón, 2010; Larsson & Ryvarden, 2021).

The species has Eurasian distribution from Norway and Sweden to Spain and Turkey (Bernicchia & Gorjón, 2010; Eriksson & Ryvarden, 1973), as well as in the distant parts of the range in North Urals (Kotiranta & Penzina, 1998) and China (Dai, 2011). Its occurrence is rare in all parts of its natural range (Hjortstam, 1980). The fungus called *Athelopsis lacerata*...

was reported by Gates (2009) from Tasmania, but the identity of the Tasmanian material with this taxon is difficult because of large geographical disjunction.

The fungus grows on decayed coniferous wood (Eriksson & Ryvarden, 1973), especially strongly decayed wood of *Pinus*; and has also been recorded on *Sarothamnus* (Larsson & Ryvarden, 2021).
A number of authors put this species in the genus *Amylocorticium* because of the amyloid spore wall (Hjortstam, 1980; Hjortstam & Ryvarden, 1979; Larsson & Ryvarden, 2021). Molecular data (Binder et al., 2010) confirmed its phylogenetic position in the order Amylocorticiales. However, its generic position is not yet clear; DNA sequences show its relation to *Amyloxenasma*, whereas basidia and spore shape have similarity with *Melzericium*.

**Specimen examined:** Białowieża Primeval Forest, near Topilo village, compart. No. 601B, Salicetum pentandro-cinerea, on dead, mostly corticated branches of Salix cinerea, 7–13 mm diam., and on old thalli of Parmelia sulcata, coll. M. Wołkowycki 18 IX 2020 (BLS M-4372).

![Figure 5](image.png)

**Figure 5** *Amylocorticium laceratum* BLS M-4372: (A) vertical section through basidioma; (B) subicular hyphae; (C) fragment of hymenium; (D) basidia; (E) basidiospores. Scale bars: for A, C–E = 10 μm; for B = 5 μm.
**Hyphoderma transiens** (Bres.) Parmasto (Hyphodermataceae, Polyporales)

Figure 1C

The species is distinguished by its odontoid hymenial surface usually with scattered aculei and presence of various tinges of ochraceous, rich crystalline deposits in the subhymenium, scarce subcylindrical enclosed leptocystidia, and middle-sized [(7.5–)8.5–10.5 μm long], cylindrical basidiospores. Micromorphology of this fungus was illustrated earlier by Yurchenko and Kotiranta (2011).

The species has large natural range, situated predominantly in warm-temperate areas. In Europe the range extends from Britain, Sweden, and Estonia to Portugal, Italy, Croatia, and Ukraine (Bernicchia & Gorjón, 2010). It was also recorded in Madeira (Tellera et al., 2008), Azores (Tellera et al., 2009), and Canary Islands (Beltrán-Tejera et al., 2015). In Asia it was reported from Russian Caucasus, Georgia, Azerbaijan, northeast Turkey (Ghobad-Nejhad et al., 2009), Iran (Ghobad-Nejhad & Hallenberg, 2012), India (Sanyal et al., 2017), Middle Urals (Shiryaev et al., 2010), China (Dai, 2011), and Japan (Maekawa, 2021). There are records of the material, named *H. transiens*, from Brazil (Chikowski et al., 2020; Hjortstam & Bononi, 1987), and named *Hyphoderma aff. transiens*, from Cameroon (Spirin & Ryvarden, 2020). There are two records of this species in GBIF, belonging to Poland, based on specimens in GB herbarium: GB-80037 (collected in 1962) and GB-80036 (collected in 1973).

The fungus grows saprobiically mostly on hardwood (*Fagus*, *Quercus*), and has also been recorded on *Tilia*, *Cornus* (Bernicchia & Gorjón, 2010; Volobuev & Arzhenenko, 2018), and *Ulmus* (Shiryaev et al., 2010). Our specimens indicate a distinct preference of this fungus to the dead wood of *Tilia cordata* in *Tilio-Carpinetum* forest association in the study area.

**Leptosporomyces fuscostratus** (Burt) Hjortstam (Atheliaceae, Atheliales)

Figures 1D, 6

The species is distinguished by the following main features: distinctly pellicular, wide basidioma with dark cream hymenial surface, quickly turning brown-black from KOH; well-developed subicum, consisting of brown hyphae near substratum; encrusted hyphae in middle subicum; small-sized basidia [10–12(–13.5) × 3.2–4(–4.5) μm]; lack of cystidial elements; small spores [(3–)3.2–3.7(–4.5) × 2–2.8 μm]. The hyphae of the middle subicum are pale brown, and turn into colorless subbasidial ones. The walls of subicular hyphae can be described as nearly thickened. Wall of many spores looks slightly thickened at ×1000 magnification.

The species has a broad distributional range in the northern hemisphere. In Europe it extends from Ireland, Norway, and Finland to Spain, Italy, and Croatia (Bernicchia & Gorjón, 2010). In Asia the localities are scattered from the Caucasus region and Middle Urals to Kamchatka and Primorye (Kotiranta et al., 2016; Shiryaev et al., 2010; Zmitrovich, 2008), China (Dai, 2011), and Japan (Maekawa, 2021). It is known to be found in Canada and USA, including Florida (Ginns & Lefebvre, 1993). There was a record of this species for Poland in GBIF, based on a specimen in the herbarium of Gothenburg University (GB), collected in 1963 (GB-107190).
The fungus grows predominantly on decayed gymnosperm wood: *Picea, Pinus, Larix, Abies, Pseudotsuga, Thuja* (Bernicchia & Gorjón, 2010; Ginns & Lefebvre, 1993; Kotiranta et al., 2016; Shiryaev et al., 2010; Zmitrovich, 2008). In North America it was also recorded on *Acer* and *Populus*, and supposedly considered as a psychrophilic species (Ginns & Lefebvre, 1993).

The fungus under the name *L. fuscostratus* was published for Poland only once by Karasiński et al. (2015), from Kampinos and Białowieża national parks. In this source *Confertobasidium olivaceolalbum* (Bourdot & Galzin) Jülich is noted as a synonym of *L. fuscostratus*. However, after the publication by Ginns and Lefebvre (1993), the current name accepted for *C. olivaceolalbum* is *Scytinostromella olivaceolba* (Bourdot & Galzin) Ginns & M.N.L. Lefebvre. The latter is a fungus, having rare skeletal hyphae and fusiform gloeocystidia in hymenium (Bernicchia & Gorjón, 2010). Both types of elements were not observed in our specimen, and hence we address it as *L. fuscostratus*, and confirm this species for Polish mycobiota.

Odonticium septocystidiatum (Burt) Zmitr. & Spirin (Irpicaceae, Polyporales)
Syn.: Candelabrochaete septocystidia (Burt) Burds.; Phanerochaete septocystidia (Burt) J. Erikss. & Ryvarden
Figures 1E, 1F, 3B

The species is identifiable by its brown ochraceous hymenial surface in mature basidiomata, large (60–145 µm long), semi-immersed cystidia, having 4–11 simple septa and thus consisting of short cells, absence of clamps at all septa, and small-sized, (5.5–6–7(–8) × 1.8–2 µm, allantoid basidiospores. Granules of resinous matter are abundant on hyphae and cystidia; this matter is yellow in water, but turns brown or orange-brown in KOH. The fungus can develop large basidiomata, 10–20 cm long and more. The micromorphology pictures for this species were published by Eriksson et al. (1978), Martini (2017), and, Volobuev and Arzhenenko (2018).

The natural range of the species includes mostly warm-temperate areas. It is known to be found in Europe (from Norway and Finland to Spain and Ukraine; Bernicchia & Gorjón, 2010), and Canary Islands (Beltrán-Tejera et al., 2013). In Asia it was documented from Caucasus region (Bernicchia & Gorjón, 2010), Iran (Ghobad-Nejhad et al., 2009; Ghobad-Nejhad & Hallenberg, 2012), Middle Urals (Shiryaev et al., 2010), and Kyrgyzstan (under the name Odonticium raitviiiri Parmasto; Eriksson & al., 1978). In North America it was reported from seven states of USA situated in the north, east, and northeast of the country (Gins & Lefebvre, 1993). Type locality of the species is in Jamaica (Parmasto et al., 2009). Moreover, there are records from Brazil (Hjortstam & Ryvarden, 2007) and Australia (Bougher & Barrett, 2020).

The fungus grows on decayed wood of angiosperms (Eriksson et al., 1978), including Populus tremula (Volobuev & Arzhenenko, 2018), Tilia and Ulmus (Shiryaev et al., 2010), on the wood and bark of Acer, Betula, Liriodendron, seldom on gymnosperms – Pinus (Gins & Lefebvre, 1993).

Owing to having clampless hyphae, this species was added in the genus Phanerochaete; because of the presence of septocystidia, it was classified in the genera Candelabrochaete and Odonticium. However, molecular phylogeny studies suggested the natural position of the species in one clade with Ceriporia and Leptoporus (Justo et al., 2017; Li et al., 2022). Consequently, the species seems to belong to the Irpicaceae family.

Phlebia cretacea (Romell ex Bourdot & Galzin) J. Erikss. & Hjortstam (Meruliaceae, Polyporales)
Syn.: Cabalodontia cretacea (Romell ex Bourdot & Galzin) Piątek
Figures 2A, 7

The species is distinguished by the presence of small (21–28 × 3.5–4 µm), capitate cystidia, and narrow, allantoid basidiospores (Q=4.2–5.4). The capitulum of some cystidia bears a cap of amorphous, colorless matter, easily dissolvable in KOH. Subicular hyphae in our specimen are associated with abundant coccoid algae.
Figure 7 *Phlebia cretacea* BLS M-3745: (A) vertical section through basidioma; (B) subicular hyphae; (C) cystidia; (D) basidioles; (E) basidia; (F) basidiospores. Scale bars: for A = 20 μm; for B, D–F = 5 μm; for C = 10 μm.

The species’ natural range includes Europe (Norway, Sweden, Finland, Estonia, France, Belgium; Bernicchia & Gorjón, 2010) and North America – Canada and USA, where it is rare (Ginns & Lefebvre, 1993). An isolated locality in the southern pre-Urals was also reported to
have this species (Safonov, 2015). There are four records of this species for Poland in GBIF, based on specimens in GB herbarium, collected in 1973: GB-115560, 115561, 115562, 115563.

The fungus grows on decaying wood of gymnosperms, e.g., decorticated wood of *Pinus* and *Picea* (Eriksson et al., 1981), and on *Thuja* (Ginns & Lefebvre, 1993). It has a tendency to inhabit semi-open habitats (Eriksson et al., 1981).

*Phlebia subulata* J. Erikss. & Hjortstam

Figures 2B, 2C, 8

The species is distinguished by basidioma of hard corneous consistency in dry state, densely arranged, narrow [1–2(–3) μm wide] subicular hyphae, presence of scarce subulate leptocystidia, and small-sized [3.7–4(–4.3) × 2.4–2.6(–3.2) μm], ellipsoid basidiospores (Q=1.5–1.7). Subiculum in our specimen is associated with abundant coccoid algae.

The natural range of this fungus includes Europe (from Norway and Finland to Spain, Serbia, and Ukraine; Bernicchia & Gorjón, 2010), and Middle Siberia (Kotiranta & Shiryaev, 2015). This species has been reported from Belarusian part of Białowieża Primeval Forest (Yurchenko, 2020). There is a record of the species from Poland in GBIF, based on a specimen from GB herbarium GB-118046, collected in 1973.

*Steccherinum* albidum Legon & P. Roberts (Steccherinaceae, Polyporales)

Figures 2D, 2E, 3C, 3D

The species is distinguished by effused basidioma, whitish hymenial surface with pale ochraceous tinge, comparatively long (0.7–1.7 mm), fairly slender (0.09–0.16 mm diam.), densely arranged (8–11/mm) hymenophoral aculei, and minute [(2.5‒)3‒3.3 × (1.2‒)1.3‒1.5 μm], suballantoid basidiospores. The species protologue was based on a single specimen (Legon & Roberts, 2002). According to the original diagnosis, the fungus has effused-reflexed basidioma, less dense (5–6/mm), but longer (2–3 mm) aculei, and slightly larger spores [3‒3.5(‒4) × 1.5 μm], than in our material. Besides, skeletal elements in our specimen were observed only in basal parts of pseudocystidia, and sterile margin is narrow (about 0.5 mm) or absent. Suballantoid spores is an unusual feature for the genus *Steccherinum* in general. Our specimen can be named more correctly as *S. albidum* s.l., until richer material is collected for this little-known taxon.

The distributional range of the species includes the type locality in Britain, on dead wood of *Fagus* (Legon & Roberts, 2002), and two localities in Switzerland (GBIF data, occurrences SWISSFUNGI-CH-633787 and -744524). Moreover, a specimen published under the name *Steccherinum albidum* aff. was found in Mexico (Spirin & Ryvarden, 2016); it has larger spores, than in the European material.

Figure 8 *Phlebia subulata* BLS M-4040: (A) vertical section through basidioma; (B) hyphae in subicular texture; (C) separate subicular hyphae; (D) cystidia; (E) hyphidia; (F) basidioles; (G) basidia; (H) basidiospores. Scale bars: for A = 20 μm; for B, C, H = 5 μm; for D–G = 10 μm.

*Tubulicrinis calothrix* (Pat.) Donk (Hymenochaetaceae, Hymenochaetales)

Figures 2F, 3E, 3F, 9

The species is distinguished by lyocystidia, which have apically asymmetrically thickened wall, and often bear a cap of crystals that are partially dissolvable in KOH. Some amount of cystidia have symmetrical wall thickening; sometimes this symmetry depends on cystidium projection on microscopic slide. Thus for reliable species identification, at least 20 cystidia should be studied.
The species has hemicosmopolitan distributional range, with a preference for warm-temperate regions. Type locality of it is in Tunisia, North Africa (Parmasto et al., 2009). In Europe it is known to be found from Norway and Finland to Portugal, Italy, and Greece (Bernicchia & Gorjón, 2010). Asian part of the range includes Turkey (Bernicchia & Gorjón, 2010), Middle Urals (Shiryaev et al., 2010), Middle and East Siberia (Kotiranta & Shiryaev 2015; Kotiranta et al., 2016; Shiryaev & Kotiranta, 2015), Primorye (Viner & Kokaeva, 2017), China (Dai, 2011), and Japan (Maekawa, 2021). In North America it is known to occur in Canada and USA (Ginns & Lefebvre, 1993). Other regions where the species was found include Canary Islands (Beltrán-Tejera et al., 2013), Venezuela (Liberta & Navas, 1978), Hawaii (Gilbertson et al., 2001), and Réunion (Hjortstam & Ryvarden, 2007). There were 7
records of this species in GBIF, belonging to Poland, based on specimens in GB herbarium and collected in 1973: GB-100377, 100378, 100379, 100380, 100381, 100382, 100383.

The fungus grows mostly on dead wood of Pinus, Picea, Larix, Abies (Bernicchia & Gorjón, 2010; Kotiranta & Shiryaev, 2015; Kotiranta et al., 2016; Shiryaev & Kotiranta, 2015; Shiryaev et al., 2010); in North America it is known to grow on Pseudotsuga, Tsuga, Quercus (Ginns & Lefebvre, 1993); in Canary Islands it occurs on unusual substrata like Euphorbia (Beltrán-Tejera et al., 2013) and Cystus (Beltrán-Tejera et al., 2015). In Poland the fungus was found on an unusual host too (Populus tremula).

Discussion

The number of species of the fungi within a country is not a fixed value, since new species are added almost every year to the country list. This can be attributed to inclusion of new areas for collection, thorough examination of habitats, studying more herbarium material, taking into account new taxonomic publications, growth of taxonomic experience of mycologists, and supposedly also expansion of the natural ranges of the species due to changes in environment. The effectiveness of the process of studying corticioid fungal diversity in Poland can be evaluated from our data. Most of the herbarium material from this study was collected during three years and only from three forested areas in the northeast part of the country. The research added eight species to the biota: Acanthobasidium norvegicum, Amylocorticium laceratum, Hyphoderma transiens, Odonticium septocystidiatum, Phlebia cretacea, Ph. subulata, Stecherinum albidum, and Tubulicrinis calothrix, which constitutes about 3% of the total corticioid fungal diversity known in 2003 (Wojewoda, 2003). The specimens of new species constitute 2.2% of the total number of collections examined. All nine species described in this paper were found in Białowieża Primeval Forest, but they are still not recorded in Knyszyn and Piska Primeval Forests. It should be noted, that all nine species were found out of the borders of Białowieża National Park, a core of Primeval Forests, which is a special protected area with strict regulation for collecting fungi. From the nine species described above, only Phlebia subulata was known from the Belarusian part of Białowieża Primeval Forest.

We have found that the records of five species from Poland (Hyphoderma transiens, Leptosporomyces fuscocrastrus, Phlebia cretacea, Ph. subulata, Tubulicrinis calothrix) were added earlier in the GBIF database (https://www.gbif.org). All of them were based on specimens from GB herbarium (University of Göteborg, Sweden). We confirmed these species from the recently collected original material.

From nine species discussed, six (Amylocorticium laceratum, Hyphoderma transiens, Leptosporomyces fuscocrastrus, Odonticium septocystidiatum, Ph. subulata, Tubulicrinis calothrix) have Eurasian or broader distribution range and three (Acanthobasidium norvegicum, Phlebia cretacea, Stecherinum albidum) have European or Euro-American distribution. Two species (Hyphoderma transiens, Odonticium septocystidiatum) occur predominantly in warm-temperate regions belonging to nemoral and mediterranean biomes. Along with identified species, about 14% of the studied specimens still belong to unclear material without specific and sometimes without generic epithet, and suggests the need for further biodiversity studies.
Financing. The work of E. Yurchenko was supported by grant BPN/SZN/2021/1/00001 within the framework of the program NAWA “Solidarni z Białorusią – Solidarni z naukowcami” (2022). The work of M. Wołkowycki got support from the grant POPC.02.03.01-00-0063.18-00 “e-Puszcza. Podlaskie cyfrowe reponytorium przyrodniczych danych naukowych” (2019–2022).

Authors’ Contributions. EY: creating the concept of the paper, identification of specimens, writing the main text, preparation of illustrations, MS formatting; MW: planning field works, collecting specimens, managing the herbarium and photographic bank, preliminary identification of specimens.

Acknowledgments. We are thankful to Konrad Wilamowski (Institute of Forest Sciences, Białystok University of Technology) for the help with the SEM images and usual digital photographs of the fungi. The authors are grateful to the two anonymous reviewers for critical consideration of the manuscript.
